

## Describing an Algorithm by Hopcroft

David Gries\*

Received 5. 7. 1972

*Abstract.* We give an algorithm, its correctness proof, and its proof of execution time bound, for finding the sets of equivalent states in a deterministic finite state automaton. The time bound is  $K \cdot m \cdot n \cdot \log n$  where  $K$  is a constant,  $m$  the number of input symbols, and  $n$  the number of states. Hopcroft [3] has already published such an algorithm. The main reason for this paper is to illustrate the use of communicating an algorithm to others using a structured, top-down approach. We have also been able to improve on Hopcroft's algorithm by reducing the size of the algorithm and correspondingly complicating the proof of the running time bound.

### Introduction

In [3], Hopcroft gives an algorithm for minimizing the number of states in a finite automaton. The running time has a bound  $K \cdot m \cdot n \cdot \log(n)$  where  $K$  is a constant,  $m$  is the number of input symbols, and  $n$  is the number of states. Previous algorithms ran in time proportional to  $mn^2$  or worse. Hopcroft's algorithm is thus a significant achievement.

Unfortunately the algorithm, its proof of correctness and the proof of running time, are all very difficult to understand. We present here a "structured", top-down approach to the presentation of the algorithm which makes it much clearer. One technique in achieving this is to present the correctness proof and algorithm hand-in-hand. In fact, once a few details of the proof are known, the algorithm is obvious. The correctness proof itself consists of a few simple lemmas each of which can be proved in a few lines.

Such a structured approach to presenting an algorithm seems to be longer and require more discussion than the conventional way. If the reader wishes to complain about this, he is challenged to first read Hopcroft's original paper and see whether he can understand it easily. The advantages of our approach will then be clear.

While we present the algorithm in top-down fashion, the reader should realize that it wasn't fully developed in this manner. A proof of a theorem may be neat and elegant, but this does not say that the proof was actually thought of in the same manner as it was presented. The same holds for programs and their descriptions.

The proof of the time bound is based on Hopcroft's work. However, it is important to notice that part of the proof given here depends on proving that a relation between values of variables remains invariant during execution of the algorithm, and this proof turns out to be significantly easier to follow than

---

Hopcroft's. We have also been able to significantly cut down on the size of the program and the data structures needed, by complicating the proof of the running time. Our algorithm is therefore different in a few aspects from Hopcroft's.

### Problem Definition

Let  $A = (S, I, \delta, F)$  be a deterministic finite automaton, where  $S$  is a finite set of states,  $I$  is a finite set of input symbols,  $\delta$  is a mapping from  $S \times I$  into  $S$ , and  $F \subseteq S$  is the set of final states. No initial state is specified since it is of no importance in what follows. The mapping  $\delta$  is extended to  $S \times I^*$  in the usual manner where  $I^*$  denotes the set of all finite strings (including the empty string  $\epsilon$ ) of symbols from  $I$ . States  $s$  and  $t$  are said to be *equivalent* if for each  $x \in I^*$ ,  $\delta(s, x) \in F$  if and only if  $\delta(t, x) \in F$ . We denote the empty set by  $\phi$ . We want an algorithm which finds equivalent states of a finite automaton.

*Example.* Consider the automaton with  $S = \{a, b, c, d, e\}$ ,  $I = \{0, 1\}$ ,  $F = \{d, e\}$ , and  $\delta$  is given by the arcs of diagram of Fig. 1 in the conventional manner.  $a$  is not equivalent to  $b$  since  $\delta(a, 0) \in F$ ,  $\delta(b, 0) \notin F$ . The final states  $d$  and  $e$  are *not* equivalent since  $\delta(d, 0) \in F$  but  $\delta(e, 0) \notin F$ .

Fig. 1. Finite state automaton

### The Basic Algorithm

We are now ready to begin our discussion of the algorithm. The following discussion may seem slightly circuitous. We present it in this way so that the final algorithm is easy to understand and easy to prove correct.

**Definition 1.** A partitioning of the states into blocks  $B_1, B_2, \dots, B_p$  is acceptable if (a) no block contains both a final and a nonfinal state, and (b) if  $s$  and  $t$  are equivalent states then they are in the same block.

As an example, we present the following lemma:

**Lemma 2.** The partitioning  $B_1 = F$ ,  $B_2 = S - F$  is acceptable.

*Proof.* Part (a) of definition 1 is clearly satisfied. Secondly, since a final and a nonfinal state cannot be equivalent, (b) is satisfied. Q.E.D.

We wish to write an algorithm which generates the single partitioning such that two states  $s$  and  $t$  are equivalent if and only if they are in the same block. The following lemma characterizes this partitioning.

**Lemma 3.** *A partitioning  $B_1, B_2, \dots, B_p$  gives the blocks of equivalent states if and only if (a) the partitioning is acceptable and (b) for each pair of blocks  $B_i, B_j$  and symbol  $a \in I$ ,*

$$s, t \in B_i, \quad \delta(s, a) \in B_j \quad \text{implies} \quad \delta(t, a) \in B_j. \quad (1)$$

*Proof.* Suppose a partitioning is not acceptable. Then either a block contains a final and a nonfinal state (which can't be equivalent), or two equivalent states are in different blocks. In either case, the partitioning obviously doesn't yield the blocks of equivalent states.

Suppose (b) doesn't hold and the partitioning is acceptable. Thus we have (for some  $s, t, B_i, B_j$ , and  $a$ )

$$s, t \in B_i, \quad \delta(s, a) \in B_j, \quad \delta(t, a) \notin B_j.$$

Since  $\delta(s, a)$  and  $\delta(t, a)$  are in different blocks, they cannot be equivalent. Hence there exists a string  $x \in I$  such that

$$\delta(\delta(s, a), x) \in F, \quad \text{and} \quad \delta(\delta(t, a), x) \notin F \quad (\text{or vica versa}).$$

Hence  $\delta(s, ax) \in F$ ,  $\delta(t, ax) \notin F$  and  $s$  and  $t$  are not equivalent but are in the same block.

To prove sufficiency, suppose that both (a) and (b) hold. Consider any two states  $s$  and  $t$  in a block  $B_i$ . We need only show that  $s$  and  $t$  are equivalent. We can easily prove by induction on the length of the string  $x$ , that  $\delta(s, x)$  and  $\delta(t, x)$  are always in the same block. Since a block cannot contain both a nonfinal and final state, the theorem is proved. Q.E.D.

We can restate Lemma 3 slightly to describe how one can refine an acceptable partitioning to get another one:

**Lemma 4.** *Let  $B_1, \dots, B_p$  be an acceptable partitioning. Suppose there are two blocks  $B_i$  and  $B_j$  and a symbol  $a$  such that*

$$s, t \in B_i, \quad \delta(s, a) \in B_j, \quad \text{but} \quad \delta(t, a) \notin B_j. \quad (2)$$

*Then  $s$  and  $t$  are not equivalent states, and we get a new acceptable partitioning by replacing  $B_i$  by the two blocks*

$$\{s \in B_i \mid \delta(s, a) \in B_j\} \quad \text{and} \quad \{s \in B_i \mid \delta(s, a) \notin B_j\}. \quad (3)$$

We leave the proof to the reader. This splitting of  $B_i$  as described is called *splitting  $B_i$  with respect to the pair  $(B_j, a)$*  or simply *splitting  $B_i$  wrt  $(B_j, a)$* . We now write the following algorithm:

$B_1 \leftarrow F; \quad B_2 \leftarrow S - F; \quad [\text{initially there are two blocks}]$  (4)  
**while**  $\exists a, B_i, B_j$  such that (2) holds **do**  
     *SPLIT*: split  $B_i$  wrt  $(B_j, a)$   
**end**

The algorithm must terminate since each execution of the loop statement *SPLIT* adds a new block, and the number of blocks in an acceptable partition can be no greater than the number of states of the finite automaton.

To show that after execution the partitioning yields the block of equivalent states, we use the following theorem about loops of the form "**while**  $B$  **do**  $S$  **end**" where  $S$  is a sequence of statements and  $B$  and  $P$  are relations (see Hoare [1]):

$$P \wedge B\{S\}P \text{ implies } P\{\text{while } B \text{ do } S \text{ end}\}P \wedge \neg B \quad (5)$$

which means: if the truth of relations  $P$  and  $B$  before execution of sequence  $S$  implies the truth of  $P$  after execution of  $S$ , then the truth of  $P$  before executing "**while**  $B$  **do**  $S$  **end**" implies the truth of  $P$  and falsity of  $B$  after execution, providing the loop terminates.

For algorithm (4), let  $P$  be the relation "the partitioning is acceptable". By Lemma 2,  $P$  is true just before execution of the **while** loop, while by Lemma 4 execution of  $S$  always yields an acceptable partitioning. The relation  $B$  is " $\exists a, B_i, B_j$  such that (2) holds". Thus,  $P$  and  $\neg B$  hold after execution of the loop, but these are the sufficient requirements described in Lemma 3 for the final partitioning to be the described one.

Note that execution of algorithm (4) says nothing about the order in which the triples  $(a, B_i, B_j)$  are chosen for splitting. Hence the order does not matter. Let us get closer to our final algorithm by describing something about this ordering. Our refinement (6) determines all splittings wrt a pair  $(B_j, a)$  and then performs *all* these splittings at the same time.

$B_1 \leftarrow F; \quad B_2 \leftarrow S - F;$  (6)  
**while**  $\exists a, B_i, B_j$  such that (2) holds **do**  
     Determine the splittings of all blocks wrt  $(B_j, a)$ ;  
     Split each block as just determined.  
**end**

The algorithm is not very efficient, since we must at least check every triple  $(a, B_i, B_j)$  for a pair  $s, t$  such that  $s, t \in B_i$ ,  $\delta(s, a) \in B_j$  but  $\delta(t, a) \notin B_j$ . In fact it looks like at least an  $m n^2$  algorithm. Let us consider the possibility of maintaining a list  $L$  of all pairs  $(B_j, a)$  wrt which some blocks may have to be split. Another way to put it is that if we *know* it is not necessary to split any  $B$  (including  $B_j$  itself) wrt a pair  $(B_j, a)$  we *won't* put that pair on the list. We can then keep splitting until the list  $L$  becomes empty.

We must of course prove that we can correctly maintain such a list  $L$ . But let us first look more closely at what splitting does, and some consequences we can draw from this.

The result of splitting all blocks wrt  $(B_j, a)$  is that *any* future block  $B$  (including the final blocks) satisfies *one* of the following:

- (a) for all  $s \in B \quad \delta(s, a) \in B_j$ , or (7)  
 (b) for all  $s \in B \quad \delta(s, a) \notin B_j$

Assertion (7) certainly holds for the blocks resulting from the splitting, and since each future block is a subset of one of these, (7) must continue to be true as the algorithm progresses. It should also be quite clear that this is the only result that splitting accomplishes. This discussion yields the following simple lemma.

**Lemma 5.** *Suppose all blocks have been split wrt  $(B_j, a)$ . Then there is no need to split any future block wrt  $(B_j, a)$ .*

This next lemma is important; without it, we would not be able to have running time proportional to  $m \cdot n \cdot \log(n)$ .

**Lemma 6.** *Suppose a block  $B_j$  is split into blocks  $\bar{B}_j$  and  $\tilde{B}_j$ . Consider a symbol  $a$ . Splitting all blocks wrt to any two of the three pairs  $(B_j, a)$ ,  $(\bar{B}_j, a)$ , and  $(\tilde{B}_j, a)$  performs the same function as splitting all blocks wrt all three pairs.*

*Proof.* Suppose we split all blocks wrt  $(B_j, a)$  and  $(\bar{B}_j, a)$ . This implies that each future block  $B$  satisfies one of the following:

- $s \in B$  implies  $\delta(s, a) \in B_j$  and  $\delta(s, a) \in \bar{B}_j$ , or
- $s \in B$  implies  $\delta(s, a) \in B_j$  and  $\delta(s, a) \notin \bar{B}_j$ , or
- $s \in B$  implies  $\delta(s, a) \notin B_j$  and  $\delta(s, a) \in \bar{B}_j$ , or
- $s \in B$  implies  $\delta(s, a) \notin B_j$  and  $\delta(s, a) \notin \bar{B}_j$

Since  $\bar{B}_j \cup \tilde{B}_j = B_j$  and  $\bar{B}_j \cap \tilde{B}_j = \emptyset$ , we infer that one of the following holds:

- $s \in B$  implies  $\delta(s, a) \in \tilde{B}_j$ , or
- $s \in B$  implies  $\delta(s, a) \notin \tilde{B}_j$

This is precisely what splitting all blocks wrt  $(\tilde{B}_j, a)$  accomplishes (see (7)). We leave to the reader to prove the rest of the theorem (in the same fashion)—that splitting wrt  $(\bar{B}_j, a)$  and  $(\tilde{B}_j, a)$  accomplishes the task of splitting wrt  $(B_j, a)$ ; and that splitting wrt  $(B_j, a)$  and  $(\tilde{B}_j, a)$  accomplishes the task of splitting wrt  $(\bar{B}_j, a)$ . Q.E.D.

As an example of the use of Lemma 6, we have the following:

**Lemma 7.** *Let the two initial blocks be  $B_1 = F$  and  $B_2 = S - F$ . For a given symbol  $a$ , it is necessary to split all blocks wrt only one of the pairs  $(B_1, a)$  and  $(B_2, a)$ .*

*Proof.* Consider Lemma 6, with  $B_j = S$ ,  $\bar{B}_j = F$ , and  $\tilde{B}_j = S - F$ . We already know that  $\delta(s, a) \in B_j$  for any symbol  $a$ , so it is not necessary to split wrt  $(B_j, a)$ . Hence we need only split wrt either  $(\bar{B}_j, a)$  or  $(\tilde{B}_j, a)$ , but not both. Q.E.D.

Now let us give the modified algorithm using a list  $L$ , and also state precisely the meaning of this list.

(8)

```

 $B_1 \leftarrow F; \quad B_2 \leftarrow S - F; \quad L = \phi;$ 
for each  $c \in I$  do1
  if  $B_1$  is smaller than  $B_2$  then add  $(B_1, c)$  to  $L$ 
  else add  $(B_2, c)$  to  $L$ ;
end;
while  $L \neq \phi$  do
   $b$ : Pick one pair  $(B_j, a) \in L$ ;
   $c$ : Determine splittings of all blocks wrt  $(B_j, a)$ ;
   $d$ :  $L \leftarrow L - (B_j, a)$ ;
   $e$ : Split each block as determined in  $c$ ;
   $f$ : /*Fix  $L$  according to the splits that occurred in step  $e$ */
    for each block  $B$  just split into  $\bar{B}$  and  $\tilde{B}$  (say) do
      for each  $c \in I$  do
        if  $(B, c) \in L$  then
           $L \leftarrow L + (\bar{B}, c) + (\tilde{B}, c) - (B, c)$ 
        else if  $\bar{B}$  is smaller than  $\tilde{B}$  then add  $(\bar{B}, c)$  to  $L$ 
        else add  $(\tilde{B}, c)$  to  $L$ 
      end
    end
  end

```

**end**

*Meaning of List  $L$ .*  $L$  is a list of pairs  $(B_j, a)$  wrt which we must attempt to split all blocks so that either (7a) or (7b) will hold for each block. If  $B_j$  is a block and  $(B_j, a) \notin L$  for some  $a$ , then either (7a) or (7b) already holds, (9) or we are assured by other means that either (7a) or (7b) will hold when the algorithm terminates.

Now compare the modified algorithm (8) with its predecessor (6). The only change is the introduction of the list  $L$  and the statements to manipulate  $L$ . If we can show that the main **while** loop of (8) terminates, and that (9) is invariantly true before and after execution of this loop, then indeed the algorithm performs the desired task.

The list  $L$  must become empty since (1) each time we use a pair  $(B_j, a)$  it is deleted in statement  $d$ ; (2) pairs are added to  $L$  in statement  $f$  only if a block is actually split into two distinct, nonempty blocks; and (3) the number of splits is bounded by  $n$ , the total number of states. Hence the algorithm terminates.

We must show that (9) is an invariantly true relation of the main loop. To do this, we again make use of the axiom

$$P \wedge B \{S\} P \text{ implies } P \{\mathbf{while } B \mathbf{ do } S\} P \wedge \neg B$$

where  $P$  is assertion (9). First of all (9) is true before execution of the loop, by Lemma 7. Thus we need only show that executing statements  $b$  through  $f$  leave (9) true.  $L$  is changed in statements  $d$  and  $f$ , so we must look at them more closely.

Statement  $d$  deletes from  $L$  the pair  $(B_j, a)$ . Since we are splitting all blocks wrt  $(B_j, a)$ , Lemma 5 gives us the right to delete it. Statement  $f$  processes each

<sup>1</sup> The **for each** statement can be interpreted as follows. Let  $I$  contain elements  $I_1, I_2, \dots, I_k$ . Then we can rewrite the statement **for each**  $c \in I$  **do**  $S$  **end** as

$$J \leftarrow 1; \text{ while } J \leq k \text{ do } c \leftarrow I_J; S; J \leftarrow J + 1 \text{ end.}$$

block  $B$  (say) that is split into  $\bar{B}$  and  $\tilde{B}$ . By Lemma 6, for a given symbol  $c$  we need only split wrt *two* of the three pairs  $(B, c)$ ,  $(\bar{B}, c)$ , and  $(\tilde{B}, c)$ . If  $(B, c)$  is in  $L$ , then statement  $f$  replaces it by  $(\bar{B}, c)$  and  $(\tilde{B}, c)$ . Suppose however that  $(B, c)$  is not in  $L$ . Statement (9) tells us we can assume that the result of splitting wrt  $(B, c)$  will be accomplished by other means before termination; hence we need only split wrt *one* of the pairs  $(\bar{B}, c)$  and  $(\tilde{B}, c)$ . Hence executing  $b-f$  leaves (9) true.

Algorithm (8) is thus correct; it performs the desired function. It remains to show that execution time is no worse than proportional to  $m \cdot n \cdot \log(n)$ . This requires some lemmas, a discussion of data structures needed to implement the states, blocks, and the list  $L$ , and some further refinements of statements  $b$  through  $f$ . While there is nothing really difficult, there is a lot of detail. We will try to structure the discussion so that the reader can stop reading as soon as he feels he understands the main thrust of the argument.

### Proof of Worst Case Running Time $O(m \cdot n \cdot \log(n))$

In Table 1 we give the time necessary to execute the various components of the program (we exclude initialization for the moment). Note that we give the *total* time spent in executing each of the substatements  $b-f$  of the main loop, and not the time required for *one* execution. The  $k_i$  are constants. Since the total time is the sum of these individual times, total execution time is of the order  $m \cdot n \cdot \log(n)$ .

One basic point is that the loop iterates a maximum of  $2 \cdot m \cdot n$  times before  $L$  becomes empty, which is proved in Lemma 8. With suitable data structures, then, statements  $b$  and  $d$  can be executed in constant time  $k_b$  and  $k_d$ , so that the total time spent in these is no more than  $2 \cdot k_b \cdot m \cdot n$  and  $2 \cdot k_d \cdot m \cdot n$ , respectively.

Statement  $f$  need only look at blocks that are actually split. The proof of Lemma 8 indicates that at most  $2 \cdot n$  blocks can be created, which shows that, at most  $2 \cdot n$  blocks can be split. Assuming that the execution time of the conditional statement "**if**  $(B, c) \in L \dots$ " of statement  $f$  is bounded by a constant  $k_f$  we see that the *total* time spent in  $f$  is no worse proportional to  $k_f \cdot 2 \cdot n \cdot m$ .

We need only analyze statements  $c$  and  $e$ , which determine splittings and then make the splits. These are the only statements whose total execution time may be proportional to  $m \cdot n \cdot \log(n)$ . And indeed the analysis gives us more

Table 1. Worst case running time analysis for the algorithm

Statement	Maximum total time spent	Proof and discussion
Main <b>while</b> loop	$2 \cdot m \cdot n$ iterations	Lemma 8
$b$	$2 \cdot k_b \cdot m \cdot n$	Lemma 8, and above
$c$	$k_c \cdot m \cdot n \cdot \log(n)$	Lemma 9, 10, below
$d$	$2 \cdot k_d \cdot m \cdot n$	Lemma 8, and above
$e$	$k_e \cdot m \cdot n \cdot \log(n)$	Lemma 10, and below
$f$	$2 \cdot k_f \cdot m \cdot n$	Lemma 8, and above
Total	$O(m \cdot n \cdot \log(n))$	

trouble. To perform the analysis we must look closer at just how to execute  $c$  and  $e$ .

Let us now look closer at splitting. Splitting a block  $B_i$  wrt  $(B_j, a)$  replaces  $B_i$  by two blocks  $\bar{B}_i$  and  $\tilde{B}_i$  which satisfy

$$\begin{aligned} s \in \bar{B}_i & \text{ implies } \delta(s, a) \in B_j; \\ s \in \tilde{B}_i & \text{ implies } \delta(s, a) \notin B_j. \end{aligned}$$

Given block  $B_i$ , let us split it by removing from it those states  $s$  such that  $\delta(s, a) \in B_j$ , and putting these states in a new block  $B_k$ , called  $B_i$ 's twin. Thus  $B_i$  is split into  $B_i$  and  $B_k$ .

In order to determine the splitting of all blocks wrt  $(B_j, a)$ , we need to make a list  $D$  (say) of all states which must be removed from blocks—which satisfy the property  $\delta(s, a) \in B_j$ . Statement  $c$  thus looks like:

$c$ : Determine the splittings of all blocks wrt  $(B_j, a)$ ; (10)  
 $D \leftarrow \phi$ ;  
**for each**  $s \in B_j$  **do**  
**if**  $\delta^{-1}(s, a) \neq \phi$  **then**  $D \leftarrow D \cup \delta^{-1}(s, a)$   
**end**

Statement  $c$  seems to have an extra test “**if**  $\delta^{-1}(s, a) \neq \phi$ ”. This test has been inserted just to make the proof of running time a bit clearer.

Statement  $e$ , which actually splits blocks, could be written as

$e$ : **for each** block  $B_i$  in the partition **do**  
 $B_k \leftarrow B_i \cap D$ ; ( $B_k$  is a newly generated block —  $B_i$ 's twin)  
 $B_i \leftarrow B_i - B_k$ ;  
**end**

While correct, statement  $e$  is too inefficient since each time it is executed it must manipulate *each* block, and this would lead to a  $m \cdot n^2$  algorithm. Hence we must refine  $e$  further to look only at blocks which have a chance of being partitioned—which contain states in  $D$ . We can also recognize a case where removing states is unnecessary. If for *all*  $s \in B$ ,  $\delta(s, a) \in B_j$  then  $\{s \in B_i \mid \delta(s, a) \notin B_j\}$  is empty. We end up with the following algorithm  $e$ :

$e$ : Split each block as just determined: (11)  
**for each**  $s \in D$  **do**  
 $BI \leftarrow$  block number in which  $s$  appears;  
**if** all  $s \in BI$  have  $\delta(s, a) \in B_j$   
**then** [no need to split block—do nothing]  
**else begin if**  $BI$  has no twin  $BK$  yet **then**  
generate  $BI$ 's twin  $BK$  and set  $BK \leftarrow \phi$ ;  
Move  $s$  from  $BI$  to its twin  $BK$   
**end**  
**end**

We are now ready to perform a worst case analysis of the total time spent in executing statements  $c$  and  $e$ . We first of all prove in Lemma 9 that the total

number of times the condition “if  $\delta^{-1}(s, a) \neq \phi$ ” of statement  $c$  is executed has a bound of  $m \cdot n \cdot \log(n)$ . This is the most difficult part of the running time proof. The *total* time spent in the rest of statement  $c$  (the statement  $D \leftarrow D \cup \delta^{-1}(s, a)$ ) and the *total* time spent in statement  $e$  are both proportional to the total number of states stored into  $D$  throughout the execution of the algorithm. We show in Lemma 10 that the total number of states put into  $D$  is bounded from above by  $m \cdot n \cdot \log(n)$ , which completes our analysis.

Two important ideas helped us in reducing the running time to  $m \cdot n \cdot \log(n)$ . The first was that if a block  $B$  is split into  $\bar{B}$  and  $\tilde{B}$  we need only split wrt two of the three pairs  $(B, a)$ ,  $(\bar{B}, a)$ , and  $(\tilde{B}, a)$ . The second was that in case we need put only one of  $(\bar{B}, a)$  and  $(\tilde{B}, a)$  in  $L$ , we should put the one whose block ( $\bar{B}$  or  $\tilde{B}$ ) contains the fewest number of states.

**Lemma 8.** *The maximum number of iterations in the main loop of algorithm (8) is  $2 \cdot m \cdot n$ .*

*Proof.* We show that the maximum number of pairs put into  $L$  is  $2 \cdot m \cdot n$ . Since each iteration deletes one pair from  $L$ , the lemma follows.

For each different block  $B$  created and for each symbol  $a$ , the pair  $(B, a)$  is put in  $L$  at most once. We need only show that at most  $2 \cdot n$  blocks can be created. Consider the binary tree consisting of the blocks created. The root node is the block consisting of all states; its two sons are the blocks  $B_1 = F$  and  $B_2 = S - F$ . For each block  $B$  its sons are the blocks  $\bar{B}$  and  $\tilde{B}$  into which it is split. The number of end nodes of this tree is bounded by  $n$ , the maximum number of blocks possible at any one time. Hence, the binary tree can contain at most  $2 \cdot n$  nodes. Q.E.D.

**Lemma 9.** *The total number of times the condition “if  $\delta^{-1}(s, a) \neq \phi$  then” of statement  $c$  (11) is executed is bounded from above by  $m \cdot n \cdot \log(n)$ .*

*Proof.* Consider a particular symbol  $\bar{a}$ . We prove below that the number of times the above condition is executed with  $a = \bar{a}$  is bounded by  $n \cdot \log(n)$ . Since there are  $m$  symbols, the lemma will follow immediately.

Let us introduce a new variable *COUNT*. Initially we set *COUNT* to 0, and we change statement  $d$  to

$d$ : **begin** if  $a = \bar{a}$  **then**  $COUNT \leftarrow COUNT + b_j$ ;  
 $L \leftarrow L - (B_j, a)$ ;  
**end**;

where  $b_j$  is the number of states in  $B_j$ . This has no effect on the output, since *COUNT* is not used elsewhere in the algorithm. But note that since  $b_j$  is the number of states in  $B_j$ , after termination *COUNT* contains the number of times the condition “if  $\delta^{-1}(s, a) \neq \phi$  then” is executed with  $a = \bar{a}$ . Thus we need only prove that  $n \cdot \log(n) \geq COUNT$ .

At each point of execution, let the blocks be called  $B_1, B_2, \dots$  and let  $K = \{B_i | (B_i, \bar{a}) \in L\}$ ,  $\bar{K} = \{B_i | (B_i, \bar{a}) \notin L\}$ . Consider the expression

$$T = n \cdot \log(n) - \sum_{B_i \in K} b_i \log b_i - \sum_{B_i \in \bar{K}} b_i \log \frac{b_i}{2}$$

where  $\log c$  means  $\log_2 c$ . Remember,  $b_i$  is the number of states in  $B_i$ . Since the total number of states is  $n$ , we always have  $n \log(n) \geq T \geq 0$ . We claim that the relation  $P$ :

$$T \geq COUNT \quad (13)$$

holds at the end of the algorithm. Using our theorem

$$P \wedge B\{S\}P \text{ implies } P\{\mathbf{while } B \mathbf{ do } S \mathbf{ end}\}P \wedge \neg B,$$

we need only show that  $P$  holds before execution of the main loop "**while**  $L \neq \phi$  **do** ... **end**", and that executing  $S$  does not change the truth of  $P$ .  $P$  certainly holds before execution of the loop, since we initialized  $COUNT$  to 0.

Consider now an execution of  $S$ . Relation (13) may change only if either  $T$  or  $COUNT$  is changed. Since only statements  $d$  and  $f$  change either one, let us analyze these carefully.

Statement  $d$  (12) changes both  $T$  and  $COUNT$ . If (and only if)  $(d)$  adds  $b_i$  to  $COUNT$ , it changes  $T$  by deleting  $(B_i, \bar{a})$  from  $L$ . If we show that this latter change also increases  $T$  by  $b_i$ , then (13) remains invariant. Deleting  $(B_i, \bar{a})$  from  $L$  has the effect of replacing (in  $T$ ) a term  $-b_i \log b_i$  by  $-b_i \log \frac{b_i}{2}$ . But

$$b_i \log b_i - b_i \log \frac{b_i}{2} = b_i (\log b_i - \log b_i + \log_2 2) = b_i.$$

Hence (13) remains invariant.

Statement  $f$  changes  $T$  by adding to and deleting pairs  $(B_i, a)$  from  $L$ . We show that  $T$  never decreases. Suppose a block  $B$  is split into blocks  $\bar{B}$  and  $\tilde{B}$ . Then  $b = \bar{b} + \tilde{b}$  where we assume without loss of generality that  $\bar{b} \leq \tilde{b}$ . Suppose  $(B, \bar{a})$  was in  $L$ . Then  $-b \log b$  is replaced by  $-\bar{b} \log \bar{b} - \tilde{b} \log \tilde{b}$ . We have

$$\bar{b} \log \bar{b} + \tilde{b} \log \tilde{b} \leq (\bar{b} + \tilde{b}) \log \tilde{b} < b \log b$$

So the change increases  $T$ . Now suppose  $(B, \bar{a})$  was not in  $L$ . Then  $(\bar{B}, \bar{a})$  is put in  $L$ . Hence a term  $-b \log \frac{b}{2}$  is replaced by  $-\bar{b} \log \bar{b} - \tilde{b} \log \frac{\tilde{b}}{2}$ . Since

$$\bar{b} \log \bar{b} + \tilde{b} \log \frac{\tilde{b}}{2} \leq \bar{b} \log \frac{b}{2} + \tilde{b} \log \frac{b}{2} = b \log \frac{b}{2},$$

$T$  again does not decrease. Hence (13) remains invariant. Q.E.D.

**Lemma 10.** *The total number of states put into  $D$  during executions of statement  $c$  (10) is bounded by  $m \cdot n \cdot \log(n)$ .*

*Proof.* Consider one particular transition  $\delta(s, a) = t$ . We show that the number of times a pair  $(B_i, a)$  with  $t \in B_i$  can be in  $L$ , is bounded by  $\log(n)$ . Hence the number of times that the particular state  $s$  is added to  $D$  because of this transition  $\delta(s, a) = t$  is bounded by  $\log(n)$ . Since there are at most  $m \cdot n$  transitions, the lemma will follow immediately.

Suppose  $t$  appears in  $B_i$ ,  $(B_i, a) \in L$ , and that the pair  $(B_i, a)$  is chosen in statement  $b$ . Then  $s$  is added to  $D$  in statement  $c$ . We claim that the next time a pair  $(B, a)$  with  $t \in B$  is put in  $L$ , that  $b \leq b_i/2$ . Why? We never have to split

wrt  $(B_j, a)$  again. If  $B_j$  itself is split into  $\bar{B}$  and  $\tilde{B}$  with  $\bar{b} \leq b_j/2 \leq \tilde{b}$ , then only  $(\bar{B}, a)$  is put in  $L$ .

The fact that if  $(B, a)$  with  $t \in B$  is put into  $L$  then  $b \leq b_j/2$ , together with  $b_j \leq n/2$ , means that such a pair  $(B, a)$  can be chosen in step  $b$  at most  $\log_2 n$  times. Q.E.D.

### The Complete Algorithm

It may be advantageous for the reader to see the whole algorithm in one piece. We present it here, with a few changes needed because of the refinements of  $c$  and  $e$ . Following the algorithm we present the data structures used in the actual PL/I implementation.

*Initialize:*  $B_1 \leftarrow F$ ;  $B_2 \leftarrow S - F$ ;  $L = \phi$ ; (14)

```

for each  $c \in I$  do
    if  $b_1 \leq b_2$  then add  $(B_1, c)$  to  $L$  else add  $(B_2, c)$  to  $L$ 
    end;
while  $L \neq \phi$  do

     $b$ : Pick one pair  $(B_j, a) \in L$ ;

     $c$ : Determine splittings of all blocks wrt  $(B_j, a)$ :
         $D \leftarrow \phi$ ;
        for each  $s \in B_j$  do  $D \leftarrow D \cup \delta^{-1}(s, a)$  end;

     $d$ :  $L \leftarrow L - (B_j, a)$ ;

     $e$ : Split each block as determined in  $c$ :
        for each  $s \in D$  do
             $BI \leftarrow$  block number in which  $s$  appears;
            if all  $s \in BI$  have  $\delta(s, a) \in B_j$  then
                else begin if  $BI$  has no twin  $BK$  yet then
                    generate  $BI$ 's twin  $BK$  and set  $BK \leftarrow \phi$ ;
                    Move  $s$  from  $BI$  to its twin  $BK$ 
                end
            end;
        end;

     $f$ : Fix  $L$  according to splits that occurred:
        for each block  $BI$  split into  $BI$  and its twin  $BK$  do
            for each  $c \in I$  do
                if  $(BI, c) \in L$  then add  $(BK, c)$  to  $L$ 
                else if  $b_i \leq bk^2$  then add  $(BI, c)$  to  $L$ 
                else add  $(BK, c)$  to  $L$ 
            end
        end  $f$ ;
    end

```

<sup>2</sup>  $b_i$  is the size of the set  $BI$ .

```

### A More Complicated Algorithm with an Easier Proof

Half the difficulty of the proof of running time is in Lemma 9. Suppose that, for each block  $B_i$  and symbol  $c$ , we maintain a set

$$\hat{B}_i(c) = \{s \in B_i \mid \delta^{-1}(s, c) \neq \phi\}$$

We can then change statement  $c$  (10) to

```

D ← φ;
For each  $s \in \hat{B}_j(a)$  do
    D ← D ∪  $\delta^{-1}(s, a)$ ;
end

```

This eliminates the need for Lemma 9. Of course the program is more complicated because we must maintain the sets  $\hat{B}_i(c)$ , which change whenever  $B_i$  changes. These sets can be maintained as doubly-linked lists so that the operations of insertion and deletion of states, and determining the size of each  $\hat{B}_i(c)$  can be performed in a fixed amount of time. This has the added advantage that if  $\hat{B}_i(c) = \phi$ , there is no need to add  $(B_i, c)$  to  $L$ . The running time is still proportional to  $m \cdot n \cdot \log(n)$  in the worst case. This is Hopcroft's original algorithm.

### The Program

The algorithm was written in PL/I, using the data structures described, and consists of 170 PL/I statements. It was not completed and run until this paper was finished (except for this paragraph and revisions). The program was tested using the PL/C compiler.

After syntax errors due to unfamiliarity with PL/I were fixed, three further errors were discovered: (1) a mistake in the input statement used to read in test data, (2) a mistake in the output statement used to print results, and (3) two cards were out of order in the minimization procedure itself. Other than that, no errors were detected.

*Acknowledgements.* I would like to thank John Hopcroft for numerous discussions about his algorithm, and Steven Brown, Donald Johnson, Tom Szymanski, and John Williams, for critically reading the manuscript and suggesting improvements. Thanks are also due to the referee, Tony Hoare, who made numerous improvements. All referees should referee the way he did.

Shimon Even, in a private communication after the type was set, noted that the same algorithm works for finite state transducers. The original partitioning must depend on the output function  $\lambda$ ; states  $s$  and  $t$  are originally in the same block iff for each symbol  $a$ ,  $\lambda(s, a) = \lambda(t, a)$ . Secondly, originally all possible pairs  $(B_i, a)$  should be placed in list  $L$ . Prof. Even also noted that Lemma 9 can be proved much more easily by showing that, for each state  $s$  and symbol,  $a$  the maximum number of times  $s \in B$  with  $(B, a)$  in list  $L$  is  $\log(n)$ . This is quite easy to show.
